

Unusual Palatal Presentation of Oral Psoriasis

(Manifestation palatale inhabituelle du psoriasis buccal)

Les lésions buccales du psoriasis sont rarement observées à l'examen clinique. D'après des rapports bien documentés sur le psoriasis buccal, les lésions varient. Elles se manifestent sous forme de plaques rouges ou blanches, ou d'ulcères. Dans le présent article, on décrit une manifestation palatale inhabituelle du psoriasis buccal sous forme d'arcs concentriques serpigneux. Le diagnostic du psoriasis intra-buccal s'appuie sur des découvertes cliniques et microscopiques.

Psoriasis is a common dermatologic disease. It can occur at any age but usually first develops during young adult life and may persist throughout a person's lifetime with periods of exacerbation and remission.¹ The exact etiology of psoriasis is unknown, but it appears to be a multifactorial disease with both genetic and psychosomatic factors.² Various triggers, such as trauma, infection and stress, may cause new episodes. The epidermal changes that occur in psoriasis seem to be related to a defect in keratinocyte proliferation. The hyperproliferative state of the affected epidermis produces a turnover rate that is up to eight times greater than normal.¹

Clinically, skin lesions appear as papules and plaques covered by silvery scales. When the scales are removed, small pinpoint bleeding is seen (Auspitz sign).¹ Skin lesions are predominantly found on the individual's extremities and scalp.³

The microscopic appearance of psoriasis varies with lesion age and activity. The early lesion shows parakeratosis and acanthosis with budding at the tips of the rete ridges and thinning of the suprapapillary plate. Polymorphonuclear leukocytes migrate through the epithelium with the formation of intraepithelial microabscesses.^{1,3,4} Although the formation of microabscesses (Munro abscesses) is characteristic of psoriasis, it is not specific to the disease nor are the microabscesses always present.³ Within the connective tissue papilla, engorgement of the capillaries occurs and a mixed inflammatory cell infiltrate is commonly seen.^{1,4} In the oral cavity, this microscopic presentation, known as psoriasisiform mucositis, is shared by psoriasis, Reiter's syndrome (a disease

of unknown origin characterized by the triad of urethritis, arthritis and conjunctivitis), benign migratory glossitis (also known as geographic tongue) and erythema migrans (lesions that are clinically and histologically similar to geographic tongue but involve oral mucosa other than the dorsum of the tongue).⁵

Oral lesions of psoriasis are rare clinical observations. Early reports of intraoral psoriasis lacked microscopic confirmation of the clinical findings. As a result, the number of cases reported and the incidence of intraoral psoriasis cannot be accurately determined from the literature. Reports of oral psoriasis that are well documented show no consistent lesion pattern. Patterns range from raised, white, scaling lesions predominantly on the palate or buccal mucosa to well-demarcated, flattened, erythematous lesions with a slightly raised, white, annular or serpiginous border.⁵ These latter lesions closely resemble geographic tongue. Oral lesions may disappear quickly or they may undergo exacerbations or remissions concomitantly with skin lesions.⁵ Diagnosis of oral psoriasis is best made when the clinical course of the oral lesion parallels that of the skin disease and is supported by microscopic findings.⁵

This report presents an unusual palatal presentation of oral psoriasis. The diagnosis of intraoral psoriasis is supported by clinical and histopathologic findings.

Case Report

A 51-year-old male presented to the graduate periodontology clinic for a complete periodontal evaluation. The patient's medical

history was evaluated by questionnaire and interview. The patient had been diagnosed with a bipolar disorder in the early 1980s and with psoriasis in the mid 1980s. There was no family history of dermatologic problems. At the time of examination and treatment, the patient was on gabapentin (Neurontin) 300 mg 3X/day for treatment of the bipolar disorder.

Extraorally, the patient presented with psoriatic lesions on the scalp and elbows (Figs. 1 and 2). No oral lesions were noted at the time of initial presentation; however, at the second visit three weeks later, asymptomatic red serpiginous linear lesions on the posterior half of the hard palate were noted (Fig. 3). A diagnosis of erythema migrans or intraoral psoriasis was made. After informed consent was obtained, a confirmatory incisional biopsy was taken using a 6-mm- diameter biopsy punch.

Microscopic examination (Fig. 4) revealed sections of mucosa surfaced with hyperparakeratotic stratified squamous epithelium with moderately developed rete pegs. Central portions of the specimen exhibited mild psoriasiform mucositis consisting of "test tube" rete pegs, thinning of the suprapapillary plate and engorgement of capillaries in the connective tissue papilla. There was mild exocytosis of inflammatory cells into the epithelium. The lamina

propria contained a mild chronic inflammatory cell infiltrate. Periodic acid-Schiff (PAS) stain for fungal elements was negative.

The lesion resolved on its own and had disappeared completely one month after the biopsy was taken.

The clinical and microscopic features of the palatal lesion were consistent with psoriasiform mucositis, and the patient's pre-existing cutaneous psoriasis supports the diagnosis of intraoral psoriasis.

Discussion

A biopsy was taken in this case to confirm the clinical impression of intraoral psoriasis. When more common causes of red lesions are eliminated (fungal infection, denture irritation), a biopsy enables the clinician to recognize and rule out more serious causes. The diagnosis then directs the clinician to the most suitable treatment for the patient's condition. In this case, the lesion was diagnosed as intraoral psoriasis and was asymptomatic; therefore, no treatment was provided. Symptomatic presentations of intraoral psoriasis have been treated with topical or local injections of corticosteroids.⁶⁻⁸ Treating oral psoriasis is unnecessary unless the patient's symptoms require attention.

In 1997, Younai and Phelan⁸ reviewed the literature and presented a case of oral mucositis with features of psoriasis. Their

Figure 2: Psoriatic lesions on the patient's elbow.

Figure 3: Clinical presentation of the patient's palate. The intraoral psoriasis presented as red serpiginous linear lesions on the posterior half of the hard palate.

Figure 4: Haematoxylin-and-eosin-stained section of tissue biopsied from the patient (medium magnification). The specimen exhibits elongation of the rete ridges into test-tube shapes, thinning of the suprapapillary plate and engorgement of the capillaries in the connective tissue papilla.

review of the English-language and European literature identified 57 reported cases of oral psoriasis. This review excluded cases of geographic tongue seen in patients with cutaneous psoriasis, resulting in a lower number than identified in the 1990 review by Sklavounou and Laskaris.⁷ Younai and Phelan found that the 46 lesions reported in the English literature could be divided into two large categories (20 white lesions and 11 erythematous lesions) and five smaller categories (6 lesions with a mixed white and red appearance, 5 ulcerative lesions, 2 vesicular lesions, 1 pustular lesion and 1 indurated lesion). The oral lesions presented on various surfaces within the oral cavity, including the lip, the buccal mucosa, the tongue, the gingiva, the palate and the floor of the mouth. The cases of psoriasis on the palate had the appearance of erythematous patches with or without ulcerations.^{5,9-13} The present case is therefore unique with its red serpiginous concentric arcs.

Weathers' article⁵ on psoriasiform lesions discussed several pathologic conditions that can involve the oral cavity. Psoriasis, Reiter's syndrome, benign migratory glossitis and erythema migrans have similar clinical and histologic findings.⁵ Therefore, when microscopic examination reveals a psoriasiform lesion, it is important to consider the clinical presentation of the patient. In the current case, the presence of skin lesions, the clinical location of the oral lesion, the microscopic presentation and the absence of the triad of symptoms known to characterize Reiter's syndrome support the diagnosis of oral psoriasis. ♦

Le Dr Richardson est diplômée du Département de parodontologie à la Faculté de médecine dentaire de l'Université des sciences de la santé de l'Orégon.

Le Dr Kratochvil est professeur agrégé et directeur du Département de pathologie buccale à la Faculté de médecine dentaire de l'Université des sciences de la santé de l'Orégon.

Le Dr Zieper est professeure adjointe au Département de pathologie buccale à la Faculté de médecine dentaire de l'Université des sciences de la santé de l'Orégon.
