Understanding the Patient with Epilepsy and Seizures in the Dental Practice

Cecilia E. Aragon, DDS, MS; Jorge G. Burneo, MD, MSPH

ABSTRACT

Epilepsy, which is characterized by the risk of recurrent seizures, is a chronic disease that affects about 200,000 Canadians at any one time. Dentists with a thorough knowledge of seizure disorders and the medications used to treat them can provide necessary dental and oral health care to these patients. In this review, we summarize current knowledge of epilepsy, seizures and antiepileptic drugs and provide information on dental-related issues, as well as guidelines for the management of an acute seizure in the dental office.

MeSH Key Words: dental care for chronically ill; emergency treatment; epilepsy/physiopathology

Epilepsy is a chronic disease characterized by the risk of recurrent seizures; its prevalence in Canada is 5.6 per 1,000 people. In developing countries, this rate can be as high as 43 per 1,000 people. According to the World Health Organization, disability due to epilepsy accounts for about 1% of the global burden of disease, as measured by disability-adjusted life-years, ranking it just after some psychiatric problems such as alcohol dependence. The global burden of epilepsy is comparable to that of breast or lung cancer.

Understanding epilepsy and seizures raises awareness of the disorder’s impact on a patient’s general medical and psychological health. Dental treatment of patients with epilepsy and seizures should be carried out by dentists who are knowledgeable about these disorders.

Seizures and Epilepsy

According to the International League Against Epilepsy, epilepsy is diagnosed when a person has 2 or more unprovoked seizures. A seizure is classified as “partial” when the electrical discharge causing it occurs in a specific area of the brain or “generalized” when the discharge affects the entire brain cortex. When there is loss of awareness, seizures are termed complex (Table 1). The classification of epilepsy is similar. Epilepsy can be partial or generalized. Based on the cause, it can be symptomatic (caused by a developmental malformation), idiopathic (when a genetic condition is responsible) or cryptogenic (when the cause is unknown).

Diagnostic tools, such as electroencephalography (EEG) and magnetic resonance imaging (MRI), are required to classify epilepsy. EEG records waves generated by the brain cortex. These waves have characteristics that allow the differentiation of normal from abnormal electrical discharges and provide information about localization. EEG amplifies the waves and transfers them to a computer for interpretation.

Differential Diagnosis

Syncope, which is characterized by loss of consciousness without any premonitory signs and symptoms, can mimic a seizure. Other conditions included in the differential diagnosis are migraine headaches, strokes or transient ischemic attacks and nonepileptic psychogenic events (or pseudoseizures), seen in association with such psychiatric conditions as conversion disorder, anxiety and depression.

Treatment of Epilepsy

Medical Treatment

Approximately 15 medications are available for the treatment of epilepsy in Canada (Table 2). The most common oral side effect of antiepileptic drugs seen in the dental office is gingival hyperplasia (Fig. 1). Although gingival hyperplasia is seen almost exclusively with the use of phenytoin, some reports have also associated it with the use of carbamazepine. Gingival hyperplasia is characterized by unusual growth of the gingival subepithelial connective tissue and epithelium, for unknown reasons; it is reversed once the drug is discontinued.

Antiepileptic drugs can achieve seizure control in approximately 50% of patients; the rate can increase to 60% after 2 trials of medications (either a combination of 2 drugs or 2 monotherapies). After a third or fourth trial, seizure control is achieved in only an additional 5% of patients. Once therapy with medications has been determined to be hopeless, the patient is referred to an epilepsy program.

Presurgical Evaluation

In an epilepsy program, the objective is to find out whether the patient is a surgical candidate by using special tests, such as prolonged monitoring videoelectroencephalography (VEEG) and structural MRI. VEEG allows confirmation of epilepsy syndrome and location of the epileptogenic focus. The behavioural changes captured by video and the focal epileptiform abnormalities in the EEG are the most important pieces of information in the presurgical evaluation. MRI identifies abnormalities of possible epileptogenicity, such as tumours and arteriovenous malformations. Hippocampal or mesial temporal sclerosis is the most common epileptogenic brain abnormality in adults with medically refractory epilepsy (Fig. 2). In this condition, “scarring” of the mesial structures of the temporal lobe occurs by an unknown mechanism, apparently related to febrile seizures during childhood. In these cases, seizures are successfully controlled with surgical removal of the seizure generator.

When VEEG and MRI are inconclusive, other neuroimaging techniques are necessary. These include single photon emission computed tomography, which measures perfusion of the brain; positron emission tomography,
which measures the metabolism of certain substances, such as glucose or flumazenil; MRI spectroscopy, which measures the metabolic profile of certain brain substances; magnetoencephalography, which evaluates the location of magnetic fields generated by epileptiform discharges, coregistered in an MRI; and functional MRI, which allows localization of vital areas of the cerebral cortex, such as language, motor, visual and sensory areas.

Subdural or depth placement of electrodes through craniotomies are indicated when the above-mentioned tools are not successful in localizing the epileptogenic area.

Surgical Treatment

Resections

Temporal lobectomy is perhaps the most common type of surgery for epilepsy. In the only randomized controlled trial of surgery versus medical treatment, the success rate was 64%. However, patients can experience a significant decline in verbal memory, which can be partly predicted through a detailed neuropsychologic evaluation.

Disconnection Procedures

Multiple subpial transections consist of small incisions perpendicular to the surface of the brain cortex to disrupt the horizontal propagation of seizures.

Section of the corpus callosum inhibits transmission between the hemispheres. This procedure is indicated in patients with drop attacks (bilateral loss of motor tone and posture control).

Treating Dental Patients with Epilepsy

General Situation

The medical literature contains little information on the influence of epilepsy in dental care. Most existing studies focus on phenytoin-induced gingival hyperplasia.

Patients living with epilepsy have special needs during dental treatment. In almost all aspects of oral health and dental status, the condition of patients with epilepsy is significantly worse than age-matched groups in the general (nonepileptic) population. Furthermore, patients who have poorly controlled epilepsy and experience frequent generalized tonic–clonic seizures exhibit worse oral health in comparison with patients who are better controlled or only have seizures that do not involve the masticatory apparatus.

The number of decayed and missing teeth, the degree of abrasion and periodontal indexes are significantly worse in patients with epilepsy. Those with epilepsy also have significantly fewer restored and replaced teeth than the general population.

The fact that dental care is only partly reimbursed, if at all, in Canada and worldwide may partly explain the problem. The negative attitude of dentists toward patients with epilepsy can also be a barrier to obtaining

appropriate dental treatment. It has been suggested that dentists are likely to consider the treatment of patients with epilepsy as cumbersome and tend to offer treatment options that are quick and simple.14

Problems that a Dentist May Encounter

Trauma

Generalized tonic–clonic seizures often cause minor oral injuries, such as tongue biting,16 but also frequently lead to tooth injuries17 and in some cases to maxillofacial trauma.18

Patients with epilepsy can be at increased risk of fracture because enzyme-inducing antiepileptic drugs (e.g., phenytoin, phenobarbital, carbamazepine) alter the metabolism and clearance of vitamin D and have been associated with osteopenia and osteomalacia.19 Of interest, increased fracture risk has also been associated with the use of benzodiazepines, antidepressants and antipsychotics, suggesting that underlying brain disease or adverse effects of the medication are responsible for falls and injuries.20

Fractures can have catastrophic effects on the lives of patients with epilepsy, and measures are available to minimize the risk of fractures, such as ensuring adequate calcium and vitamin D supplementation (a minimum of 1,000 mg and 400 IU daily, respectively) especially in patients taking phenobarbital, phenytoin or primidone.20

Periodontal Problems

Gingival overgrowth as a complication of phenytoin use has been well studied.21,22 About 50% of patients taking this medication will develop gingival hyperplasia within 12–24 months of initiation of treatment. Despite the existence of newer medications that are equally effective and have fewer side effects, phenytoin remains one of the most commonly used drugs. Evidence regarding best treatment for gingival hyperplasia is lacking. Some clinicians advocate the use of chlorhexidine, folic acid rinses or both, but excellent oral hygiene will probably prevent or significantly decrease the severity of the condition. In severe cases, surgical reduction is needed.23

The newer antiepileptic drugs produce oral manifestations only infrequently. Xerostomia and stomatitis have been reported rarely as side effects of carbamazepine,24 and rash that may involve the masticatory apparatus, frequent general trauma — is needed to assess the risk of peri- and postoperative bleeding. Bleeding as a potential side effect should be discussed with patients and their families in preparation for surgery.26

Prosthodontic Problems

In a recent analysis of the prosthodontic status of patients with epilepsy,15 it was found that compared with age-matched controls, patients with epilepsy have a tendency to become edentulous earlier. It was also found that prosthodontic treatment is suboptimal, as significantly fewer teeth are replaced, despite the fact that epileptic patients tend to have more missing teeth. Based on these findings, the authors suggested a classification for patients with epilepsy according to dental risk factors and dental manageability and provided recommendations for dental treatment.

Specific guidelines were also provided, such as discouragement of incisal restorations, use of fixed rather than removable prostheses and inclusion of additional abutments if fixed partial dentures are to be used.15 In addition, the use of metal base for complete dentures and telescopic retention with denture bases made of metal or reinforced with metal for nearly edentulous patients was recommended for those with frequent partial seizures involving the masticatory apparatus, frequent generalized tonic–clonic seizures and other seizures associated with falls.

Dermatologic Problems

Rash is a common side effect of antiepileptic drugs. Although most drug-associated rash is benign, serious rashes, including Stevens–Johnson syndrome and toxic epidermal necrolysis do occur.27 Between 5% and 7% of patients taking phenytoin and 5% to 17% of patients taking carbamazepine experience rash. The patients at highest risk for lamotrigine rash are children with a history of rash from another antiepileptic drug; 18.2% experience lamotrigine rash.28

Drug Interactions

A number of drugs prescribed by dentists can jeopardize seizure control because they interact with antiepileptic drugs. For instance, metronidazole, antifungal agents (such as fluconazole) and antibiotics (such as erythromycin) may interfere with the metabolism of certain antiepileptic drugs.29

The coadministration of fluconazole and phenytoin is associated with a clinically significant increase in phenytoin plasma concentration, and the dose of the latter may require adjustment to maintain safe therapeutic concentrations. Other anticonvulsants, such as vigabatrin, lamotrigine, levetiracetam, oxcarbazepine and gabapentin, are unlikely to interact with fluconazole.
Clarithromycin increases the plasma concentration of carbamazepine, and coadministration of these drugs should be monitored very carefully to avoid carbamazepine toxicity.\(^\text{30}\)

Valproic acid may be displaced from plasma proteins and metabolic pathways may be inhibited by high doses of aspirin; this interaction will free serum valproate concentrations resulting in subsequent toxicity.\(^\text{31}\)

---

**Seizure First Aid in the Dental Office**

If a seizure occurs while a patient is in the dental chair

1. Clear all instruments away from the patient.
2. Place the dental chair in a supported, supine position as near to the floor as possible.
3. Place the patient on his or her side (to decrease the chance of aspiration of secretions or dental materials in the patient’s mouth).
4. Do not restrain the patient.
5. Do not put your fingers in his or her mouth (you might be bitten).
6. Time the seizure (the duration of the event may seem longer than it actually is).
7. Call 911 if the seizure lasts longer than 3 minutes.
8. Call 911 if the patient becomes cyanotic from the onset.
9. Administer oxygen at a rate of 6–8 L/minute.
10. If the seizure lasts longer than 1 minute or for repeated seizures, administer a 10-mg dose of diazepam intramuscularly (IM) or intravenously (IV), or 2 mg of ativan, IV or IM, or 5 mg of midazolam, IM or IV.\(^\text{32,33}\)
11. Be aware of the possibility of compromised airway or uncontrollable seizure.

Once the seizure is over

1. Do not undertake further dental treatment that day.
2. Try to talk to the patient to evaluate the level of consciousness during the post-ictal phase.
3. Do not attempt to restrain the patient, as he or she might be confused.
4. Do not allow the patient to leave the office if his or her level of awareness is not fully restored.
5. Contact the patient’s family, if he or she is alone.
6. Do a brief oral examination for sustained injuries.
7. Depending on post-ictal state, discharge the patient home with a responsible person, to his or her family physician or to an emergency room for further assessment.

---

**Conclusions**

Advances in diagnostic technology, pharmacotherapy and understanding of neurologic processes allow dentists to understand and manage patients with epilepsy better. People with epilepsy can be safely treated in a general dental practice. A thorough medical history should be taken and updated at each visit. Seizure history must be taken into account when planning treatment. Dentists with a comprehension of seizure disorders can provide an invaluable service to their patients, providing not only oral health, but also maintaining and promoting the systemic health of these patients. *
