Developmental aberrations may result in the formation of supernumerary or extra structures. Polydactily or extra fingers or toes and supernumerary teeth are examples of such developmental duplications. Accessory or supplementary jaws are duplicated portions of jaws or entire jaws, with or without teeth.1 In the case of the maxilla, such accessory jaws are called distomus.2,3 Distomus formation is extremely rare.2 Accessory jaws may be associated with the formation of an accessory rudimentary or vestigial mouth.1 Reports indicate that distomus has been observed more commonly in association with lateral facial clefts.2 Congenital facial clefts, which have been classified by Tessier,4 may occur where embryologic processes fuse. The most common facial clefts are cleft lip and palate; the prevalence of cleft lip with or without cleft palate in the largest study to date is 1.2 per 1,000 live births.5 The incidence of lateral facial clefts in various series ranges from 0.3% to 0.67% of all facial clefts.5,6 Facial clefts associated with duplication of various oral structures have also been reported.7–11 Stoneman1 and DeGurse and others2 have reported cases of a congenital facial fistula with an accessory maxilla and teeth.

This article reports the management, over 9 years, of a patient with an accessory maxilla with supernumerary teeth and a congenital facial fistula, who required treatment due to increasingly bothersome symptoms.

**Case Report**

An 8-year-old boy was referred for assessment of a fistula that occasionally drained milk-like fluid from an opening on the left nasolabial groove of the face. The parents stated that this drainage had been present since birth. The patient had been previously diagnosed as having an incomplete facial cleft. Serial panoramic radiographs and a computed tomography (CT) scan revealed the progressive development of first 2, then 3 tooth-like structures in the left cheek in a cavity with a fluid-filled lumen. A diagnosis of odontoma was dismissed, on the basis of the appearance and position of the lesion. Rather the lesion was thought to resemble an accessory maxilla. The past medical history was otherwise unremarkable.

The patient was followed regularly with semi-annual visits over the next 7 years. A creamy-white milk-like fluid was initially expressible by palpation of a dimple of the left cheek in the nasolabial groove (Fig. 1). The volume of the drainage progressively increased over the years of follow-up, such that each time the patient smiled, he expressed the fluid spontaneously onto his cheek. This steadily increasing spontaneous drainage became distressing to the patient, to the point of being socially unacceptable. Bacterial culture and sensitivity testing of the facial discharge revealed normal skin flora with a scant growth of coagulase-negative *Staphylococcus* species. Surgery had been delayed at the request of the boy’s parents. At the age of 15 years, the
patient had a fistula on the left cheek approximately 3 cm lateral to the left oral commissure. It was secreting spontaneously or when the left cheek was rubbed.

Radiographic examination revealed a 4-cm–wide round cavity with 3 supernumerary teeth in the left maxillary sinus area (Fig. 2). In panoramic radiographs taken 6 years earlier, there were 2 premolar-like supernumerary teeth. A CT scan showed a cavity with a sharp delineation from the maxillary bone and its zygomatic process. The lesion extended from the orbital floor to the zygomatic buttress area. It did not extend into the inferior part of the left maxillary sinus or into the maxillary alveolar process. Otherwise the whole sinus was full of accessory tissue. The teeth within the lesion were attached to the bony walls of the cavity (Fig. 3a). This bony cavity was filled with fluid and connected to a cavity in the soft tissues of the left cheek (Fig. 3b).

Surgery was performed under general anesthesia. A plastic catheter was threaded into the fistula and methylene blue dye was injected into the catheter to help delineate the accessory structures connected to the fistula (Fig. 4). A vestibular incision was used to expose the entire anterior maxilla. Bone over the soft tissue capsule was removed (Fig. 5). The fistula and the soft tissues surrounding the blue-stained structures in the left cheek were removed in 1 piece. The teeth and the bony cavity, which contained a brownish liquid, were removed in a separate piece. Care was taken not to damage the parotid duct and branches of the facial nerve. The specimens were sent for histopathologic evaluation (Fig. 6).

Histologic sections revealed bone, developing teeth and a stratified squamous epithelium lining the lumen of the bony and soft-tissue cavities. Postoperative healing was uneventful and neither the lesion nor the fistula has shown any clinical or radiographic signs of recurrence in over 3 years of follow-up (Fig. 7).

Discussion

This case report presents the long-term management and closely supervised follow-up of a congenital facial fistula with an accessory maxilla and teeth. The diagnosis of incomplete facial cleft had been suggested when the patient was 6 years of age. Because the only complaint was a fistula
that was occasionally draining, the parents opted for long-term observation. The drainage progressively worsened until the patient found it intolerable and requested removal of the lesion. Serial assessments were conducted to ensure that the patient was not lost to follow-up and that the related structures near the lesion were growing and developing normally.

The development of an accessory jaw is very rare. The lesion may occur as a mass of bone containing teeth or as a complete jaw.1,2,7–11 Stoneman1 and DeGurse and others2 have suggested that some facial fistulas are vestiges of facial clefts. In this case, in addition to the accessory jaw tissue, a fistula connected the skin to a separate lumen or rudimentary mouth in the cheek. The management of such lesions must be guided by the symptoms and their potential to interfere with the development of surrounding structures. The timing of their removal depends on these 2 factors and the progressive development of bothersome symptoms. Dentists can contribute to the management of such lesions by identifying them and referring the patient for definitive management.
