Idiopathic gingival fibromatosis is a rare hereditary condition that has no specific cause. Investigations are ongoing to establish the genetic linkage and heterogeneity associated with it. This condition may manifest as an autosomal-dominant or, less commonly, an autosomal-recessive mode of inheritance, either as an isolated disorder or as part of a syndrome. Syndromic gingival fibromatosis has been associated with ancillary features such as hypertrichosis, mental retardation, epilepsy, progressive sensorineural hearing loss and abnormalities of the extremities, particularly of the fingers and toes. Autosomal-dominant forms of gingival fibromatosis, which are usually non-syndromic, have been genetically linked to the chromosome 2p21-p22 and 5q13-q22. Recently, a mutation in the son of sevenless-1 (SOS-1) gene has been suggested as a possible cause of isolated (nonsyndromic) gingival fibromatosis, but no definite linkage has been established.

Idiopathic gingival fibromatosis is a slowly progressive benign enlargement that affects the marginal gingiva, attached gingiva and interdental papilla. The fibromatosis may potentially cover the exposed tooth surfaces, causing esthetic and functional problems, and in extreme cases may distort the jaws. The gingival tissues are usually pink and nonhemorrhagic, and have a firm, fibrotic...
A 23-year-old man reported to the outpatient department of our institute complaining of pain and swelling in the gums and an inability to chew food. The patient was also concerned about the progressively increased spacing between his upper front teeth and their movement away from their original positions.

The medical history revealed that the patient’s gums had progressively enlarged over the last 6 to 7 years and that the patient had pain during mastication and increased tooth mobility, especially of all 4 first molars, 3 of which had to be extracted about 2 years before. Nothing in the patient’s medical and family history seemed related to the condition, and no associated endocrinological abnormality could be detected.

The patient was not receiving any anti-epileptic, antihypertensive or immunosuppressive medications that could contribute to the gingival enlargement. However, the patient had smoked up to 20 cigarettes a day for the past 4 to 5 years and drank alcohol about 2 or 3 times a week.

Intraoral examination revealed moderate-to-severe gingival overgrowth of a firm, dense and fibrotic consistency that involved both the maxillary and mandibular arches (Figs. 1 to 3). The loss of attachment affects at least 3 permanent teeth other than first molars and incisors.

We report here an unusual case of a nonsyndromic, idiopathic gingival fibromatosis associated with generalized aggressive periodontitis. Only one other case with such an association has been reported to date. We discuss our patient’s clinical findings, histopathologic evaluation, analysis of neutrophil function and treatment plan.

Consistency. Histopathologically, the bulbous increased connective tissue is relatively avascular and has densely arranged collagen-fibre bundles, numerous fibroblasts and mild chronic inflammatory cells. The overlying epithelium is thickened and acanthotic, and has elongated rete ridges. Unusual findings include the presence of small calcified particles, amyloid deposits, islands of odontogenic epithelium and osseous metaplasia in the connective tissue, and ulcerations of the overlying mucosa.

Aggressive periodontitis comprises another group of genetically inherited diseases that represent a severe and rapidly progressive form of periodontitis. Characteristically, these diseases tend to exhibit familial aggregation and there are no factors in the medical history that seem associated with the condition.

Aggressive forms of periodontitis are currently considered to be multifactorial diseases that develop as a result of complex interactions between specific host genes and the environment. Various factors have been identified that increase the risk of developing aggressive periodontitis, including familial aggregation, single nucleotide polymorphisms, neutrophil functional defects, antibodies to specific bacteria, herpes virus infection, smoking and stress.

Generalized aggressive periodontitis usually affects people under 30 years of age. They have a poor serum-antibody response to infecting agents and pronounced episodic destruction of the attachment and alveolar bone. The loss of attachment affects at least 3 permanent teeth other than first molars and incisors.

We report here an unusual case of a nonsyndromic, idiopathic gingival fibromatosis associated with generalized aggressive periodontitis. Only one other case with such an association has been reported to date. We discuss our patient’s clinical findings, histopathologic evaluation, analysis of neutrophil function and treatment plan.

Case History

Diagnosis

A 23-year-old man reported to the outpatient department of our institute complaining of pain and swelling in the gums and an inability to chew food. The patient was also concerned about the progressively increased spacing between his upper front teeth and their movement away from their original positions.

The medical history revealed that the patient’s gums had progressively enlarged over the last 6 to 7 years and that the patient had pain during mastication and increased tooth mobility, especially of all 4 first molars, 3 of which had to be extracted about 2 years before. Nothing in the patient’s medical and family history seemed related to the condition, and no associated endocrinological abnormality could be detected. The patient was not receiving any anti-epileptic, antihypertensive or immunosuppressive medications that could contribute to the gingival enlargement. However, the patient had smoked up to 20 cigarettes a day for the past 4 to 5 years and drank alcohol about 2 or 3 times a week.

Intraoral examination revealed moderate-to-severe gingival overgrowth of a firm, dense and fibrotic consistency that involved both the maxillary and mandibular arches (Figs. 1 to 3). The patient had generalized tooth mobility with a severe pathologic migration, especially of the upper anterior teeth. Full-mouth periodontal charting, including assessment of probing depth and clinical attachment level, revealed deep pockets throughout the mouth, and scanty plaque and calculus deposits.

The radiographic findings, which corroborated those of the clinical examination, revealed severe generalized alveolar bone loss (Fig. 4). The peripheral blood results were normal and correlated with an absence of any history of systemic disease.

Based on all these findings, a provisional diagnosis of idiopathic gingival enlargement with generalized aggressive periodontitis was made.
**Histopathologic Findings**

The attached gingiva excised from the buccal and interdental areas during surgery (Fig. 5) was immediately fixed in 10% buffered formaldehyde solution and sent for histopathologic examination. The specimen was processed and then embedded in paraffin wax. Multiple 5-mm serial sections were prepared, stained with hematoxylin and eosin, and viewed under a trinocular light microscope with flat-field objective lenses at 100× and 400× magnifications.

The microscopic evaluation of these sections revealed parakeratinized stratified squamous acanthotic epithelia with thin long rete ridges extending into the connective tissue. The underlying connective tissue showed dense wavy bundles of collagen fibres containing numerous fibrocytes and fibroblasts. Some sections in the connective tissue exhibited infiltration of chronic inflammatory cells, a few scattered multinucleated giant cells and areas of neovascularization that had red blood corpuscles within the lumen of the blood vessels (Figs. 6 to 8).

**Analysis of Neutrophil Function**

The phagocytic ability of the patient’s polymorphonuclear leukocytic cells was assessed with a nitro-blue-tetrazolium (NBT) reduction test. During this test, polymorphonuclear leucocytes (PMNLs) were stimulated with heat-killed spores of *Candida albicans* to evaluate the oxidative pathway. Normal granulocytes metabolically activated by phagocytosis reduce NBT to blue formazan. Eighty percent of the patient’s cells contained reduced blue formazan, which was the percentage of PMNLs producing a respiratory burst, thereby indicating the normal functioning of the oxygen-dependent leukocytic bactericidal system.

**Treatment**

The patient initially underwent phase 1 periodontal therapy that comprised scaling and root planing, oral hygiene instructions and adjunctive administration of systemic doxycycline (100 mg twice a day, on the first day, followed by 100 mg once a day for 14 days)\(^{23,24}\). Phase 2 therapy involved periodontal surgery in all 4 quadrants that involved an internal bevel gingivectomy combined with open-flap debridement (Figs. 9 and 10).

The patient was then referred to a specialist for orthodontic correction of malaligned teeth, followed by prosthetic replacement of the missing teeth. The patient was followed up regularly; no recurrence of gingival
overgrowth was observed 6 months after the surgery (Fig. 11).

Discussion

Gingival fibromatosis is frequently part of various syndromes, including Rutherford syndrome, Cross syndrome, Zimmerman-Laband syndrome, Prune belly syndrome, Ramon syndrome, Murray-Puretic-Drescher syndrome and Jones syndrome.6,13 Recent findings5 have identified a mutation in the SOS-1 gene that segregates the hereditary gingival fibromatosis phenotype. Identification of the specific genetic basis for hereditary gingival fibromatosis should help elucidate the pathogenic mechanisms that cause gingival enlargement.

Aggressive periodontitis is typically characterized by familial aggregation because of evidence of genetic predisposition that was derived from segregation analysis of affected families.21 Mendelian inheritance occurs, and autosomal (dominant and recessive) transmission and X-linked transmission have been proposed.21 Our patient had a diagnosis of generalized aggressive periodontitis with idiopathic gingival fibromatosis, based on his clinical findings and no history of familial aggregation. Presence of generalized aggressive periodontitis in a case of otherwise nonsyndromic gingival fibromatosis opens avenues for research into the existence of a predictable association between the 2 entities. A case of hereditary gingival fibromatosis associated with generalized aggressive periodontitis reported earlier indicated the possible emergence of a new syndrome, but no definite genetic linkage could be established.18

The results of the histopathologic evaluation of the biopsied tissues of our patient were consistent with those for fibrous gingival hyperplasia: the presence of a thickened acanthotic epithelium with elongated rete ridges and densely arranged collagen bundles with numerous fibroblasts, coupled with some sections that exhibited neovascularization and a few scattered giant cells in the underlying connective tissue. However, the histologic features of gingival fibromatosis are usually nonspecific and a definitive diagnosis should be established based on family history, clinical findings, genetic analysis, and immunologic and microbiological assessments.13,14

Neutrophils play a major cellular role in the innate immune response against invading periodontopathic microorganisms. Defective adherence, chemotaxis, phagocytosis and intracellular killing are all implicated in the increased susceptibility of the host population to periodontitis, and these PMNL functional defects are genetically transmitted.25 Recent findings support the role of neutrophil abnormalities in aggressive periodontitis and this is attributed to the chronic hyperactivated, or primed, state of the neutrophils.26 The PMNLs in patients with aggressive periodontitis are hyperfunctional; the excess activity and release of toxic products from these cells are responsible for the existing severe tissue destruction.26

In this report, the NBT reduction test used to analyze neutrophil function27,28 measures neither phagocytic nor killing ability, but is an indicator of the degree of activity in the enzyme systems that are usually triggered by phagocytosis and ultimately cause bacterial killing. Results of this test were positive for 80% of our patient’s cells, a finding that indicated that a large proportion of the neutrophils exhibited an oxidative burst.

Although a superoxide dismutase inhibitable cytochrome C-reduction test should be done to quantitatively assess the generation of superoxide to identify the hyperprimed state of the neutrophils,28 this test could not be carried out because of institutional constraints. Nevertheless, the high percentage of neutrophils that were positive during the NBT test demonstrated their ability to respond with increased metabolic activity to a bacterial or endotoxin stimulus.

Recent evidence identifies the role of environmental factors in the clinical expression of aggressive periodontitis. Smoking is a major risk factor for patients...
with generalized aggressive periodontitis; smokers have a greater incidence and severity of attachment loss than nonsmokers.29 Our patient, who was a chronic smoker, had severe attachment and alveolar bone loss.

Treatment of gingival fibromatosis is essential because it causes difficulties with mastication, speech problems, malpositioning of teeth, esthetic effects and psychological difficulties for the patient.

In a case of gingival enlargement with deep pockets and severe loss of underlying alveolar bone, an internal bevel gingivectomy with open-flap debridement is indicated.30 This surgical procedure was done for our patient to eliminate pockets, making plaque control easier; to reduce the bulbous gingival tissues; and to enable the regeneration or repair of the alveolar bone defect.

Our patient is being regularly monitored clinically and radiographically for improvement in his periodontal condition, as well as for any recurrence of gingival overgrowth. He will receive orthodontic treatment15,31 and prosthetic rehabilitation, which are appropriate follow-up strategies to surgery for gingival fibromatosis.

Conclusions

This case highlights the unusual coexistence of nonsyndromic idiopathic gingival fibromatosis with generalized aggressive periodontitis. Diagnosis was based on clinical, radiographic, histopathologic and immunologic assessment. However, further research is needed to establish a syndromic association between the 2 conditions based on genetic evaluation and linkage studies.
